### ABSTRACT

The generic and sub-generic relationships in the Boletineae (Boletales) were studied using nuclear large subunit (*nuc-lsu*), translation elongation factor 1-alpha (*tef1*), and DNA directed RNA polymerase largest subunit (*RPB1*). The Boletineae, with the exclusion of *Hydnomerulius pinastri*, was strongly supported and the status of the families Boletaceae and Paxillaceae is discussed. Members of the genus *Boletus* are found throughout the phylogeny, with the majority not closely related to the type species, *Boletus edulis*. Many of the traditional, morphologically defined genera are not supported as monophyletic and additional sampling and taxonomic revisions are needed. The majority of the Boletineae are confirmed or putatively ectomycorrhizal (ECM), but two putatively mycoparasitic lineages (one lineage of *Buchwaldoboletus lignicola* and *Chalciporus piperatus* and the second *Pseudoboletus parasiticus*) are strongly supported.

## Introduction

The suborder Boletineae (originally considered Agaricales) as a taxonomic rank was first used by Gilbert (1931), and included both poroid and gilled species. This was a step forward in bolete taxonomy, the first time gilled species were included in a concept of a 'bolete'. Since then, the generic and species concepts in the Boletineae have been dominated by those proposed by Singer (1986), which follows the inclusion of gilled species proposed by Gilbert (1931) and Smith & Thiers (1971). The broad outlines of the 'modern' Boletineae, based on multi-locus phylogenetic analyses, were presented by Binder &

Hibbett (2006). The generic-level classifications of Smith & Thiers (1971) and Singer (1986) along with current genera of Boletineae are presented in Table 1. The systems of Smith & Thiers (1971) and Singer (1986) mainly used morphological characters and chemical staining reactions, e.g. the colours produced by placing KOH on the pileipellis, to define genera. Singer (1986) also incorporated the results of chemotaxonomic studies, which identified pigments responsible for colouration and staining reactions. Chemotaxonomic data (Besl et al. 1974, 1986; Besl & Bresinsky 1977, 1979, 1997; Steglich et al. 1977; Bresinsky & Besl 1978) were not available at the time of Smith and Thiers's (1971) work.

**Table 1 – (continued)**

Boletaceae of Smith & Thiers (1971)	Boletineae of Singer (1986)	Current
		<i>Incertae sedis</i> <i>Hydnomerulius</i>
a Species of <i>Boletus</i> sensu Smith & Thiers (1971) are distributed across four genera of Singer (1986).		
b Currently classified in Sclerotermatinae.		
c Species of <i>Leccinum</i> sensu Singer are distributed across <i>Leccinum</i> and <i>Tylopilus</i> (pro parte) by Smith & Thiers (1971).		
d Species of <i>Tylopilus</i> sensu Smith & Thiers (1971) are distributed across <i>Tylopilus</i> and <i>Porphyrellus</i> sensu Singer (1986). Single Smith and Thiers.		
e Currently classified in Suillineae.		
f No molecular data available or no nuc-lsu, tef1, and RPB1.		

Morphological characters used to delimit genera and species in Boletineae include, but are not limited to: stipe ornamentation, pileipellis and stipitipellis structures, pore surface colour, pore depth, pore mouth diameter, staining reactions of bruised tissues, and staining reactions of different tissues (such as pileus context, stipe context, pileipellis, stipitipellis) to chemicals, typically KOH, 5 % ammonia solution, and FeSO<sub>4</sub>. An overview of the presence, absence, and states of key morphological characters of the genera of Boletineae is presented in Table 2. Chemical analysis of pigment production in the boletes has also been used as a taxonomic character and allowed the placement of species not previously thought to be closely related to the boletes, e.g. *Chamoniaxia* (Boletineae) and *Coniophora* (Coniophorinae), and further strengthened the separation of *Suillus* (Suillineae) from *Boletus* (Steglich et al. 1977; Besl et al. 1986; Besl & Bresinsky 1997).

Smith & Thiers (1971) placed only poroid fungi in the Boletaceae and included members of the modern Suillineae and Sclerotermatinae (Besl & Bresinsky 1997; Jarosch 2001; Binder & Bresinsky 2002a). The modern members of the Boletineae (Table 1) that are gilled, *Paxillus* and *Phylloporus*, were placed in the Paxillaceae (Smith & Thiers 1971). Singer's (1986) concept of the Boletineae is almost identical to the modern Boletales (Singer 1986; Binder & Hibbett 2006). The modern Boletineae members are distributed in the Paxillaceae and Boletaceae in Singer's (1986) classification. However, only one genus of Singer's Paxillaceae, *Paxillus* s.str. (not including *Tapinella* or *Austropaxillus* [Tapinellineae]), is included in the modern Boletineae (Binder & Hibbett 2006).

Smith and Thiers were more conservative than Singer when considering whether differences between morphological features warranted a separate genus (Smith & Thiers 1971; Singer 1986). This led Smith and Thiers to 'lump' species into larger genera than those recognized by Singer, except for the genus *Leccinum* (Smith & Thiers 1971; Singer 1986). Overall, Singer recognized 22 genera (not including families that have no modern representatives) of Boletineae and Smith and Thiers recognized 12 genera (including genera in the modern Boletineae that Smith and Thiers placed outside the Boletaceae), including *Suillus* (Table 1). However, Smith and Thiers placed *Paragyrodon* as a section of *Suillus* and stated that *Gyrodon*

*lividus* was most closely related to *Suillus*; in fact, both *Paragryodon* and *G. lividus* are members of the modern Boletineae (Paxillineae in Binder & Hibbett 2006) (see Table 1; Smith & Thiers 1971; Singer 1986; Binder & Hibbett 2006).

Some aspects of generic limits and inter-generic relationships in Boletineae have remained unclear. This is due, in part, to alternative interpretations of relatedness based on morphology (as well as lack of resolution in molecular studies). An example is provided by *Boletus*, which Smith and Thiers regarded as 'the most distinctive genus in the family'. However, Smith and Thiers's concept of *Boletus* encompasses multiple genera recognized by Singer, e.g. *Aureoboletus*, *Xerocomus*, *Xanthoconium* (Smith & Thiers 1971; Singer 1986).

Analyses of chemical characters (pigments and colourless compounds that are produced via secondary metabolisms) have been useful for separating large groups, or genera, but overall have been unable to resolve intergeneric relationships among the Boletineae (Besl & Bresinsky 1977, 1979, 1997; Besl et al. 1986; Besl et al. 1974; Binder & Hibbett 2006; Bresinsky & Besl 1978; Steglich et al. 1977). Analyses of DNA sequences have also been informative, but the molecular studies of the last 15 y have failed to resolve generic relationships in the Boletineae and have often focused on only one or a few genera at a time (Binder & Bresinsky 2002b; Binder & Hibbett 2002; Desjardin et al. 2008, 2009; Dentinger et al. 2010; Vizzini et al. 2010; Lebel et al. 2011; Halling et al. 2012a). As more taxa have been sampled in molecular studies, it has become clear that some morphology-based generic concepts do not correspond to monophyletic groups, especially in the larger genera, such as *Boletellus*, *Boletus*, *Tylopilus*, *Xerocomellus*, and *Xerocomus*, but there has been no comprehensive phylogenetic analysis of all the genera of Boletineae. Instead, many studies have focused on finding limits of individual genera or placing species into genera (Binder & Besl 2000; Binder & Bresinsky 2002b; Desjardin et al. 2008, 2009, 2011; Dentinger et al. 2010; Li et al. 2011; Halling et al. 2012a, b; Hosen et al. 2012).

Most previous molecular studies used the nuclear large subunit (nuc-lsu), which has been shown to have little resolving power in the Boletineae when used in isolation (Binder & Hibbett 2006). Continued use of nuc-lsu maintains compatibility between studies and allows placement of species into genera or cryptic forms into a family (e.g. truffle-like species), but additional loci are needed to resolve higher-level relationships in Boletineae (Binder & Besl 2000; Binder & Bresinsky 2002b; Peintner et al. 2003; Binder & Hibbett 2006; Desjardin et al. 2008, 2009; Drehmel et al. 2008; Binder et al. 2010; Dentinger et al. 2010; Vizzini et al. 2010; Lebel et al. 2011; Li et al. 2011; Halling et al. 2012a, b). Here, we present a broad phylogenetic analysis of all the major genera of the Boletineae, using three genes: nuclear large subunit ribosomal RNA (nuc-lsu), translation elongation factor 1-alpha (tef1), and DNA directed RNA polymerase II largest subunit (RPB1). Tef1 and RPB1 were chosen based on the potential they have been shown to have to resolve genera in the Boletineae in previous studies (Binder et al. 2010; Dentinger et al. 2010; Li et al. 2011; Halling et al. 2012a, b; Hosen et al. 2012). The goal of the present study was to develop a phylogenetic framework to guide further exemplar-based sampling and an eventual generic-level reclassification of the Boletineae.

## Materials and methods

**Taxon sampling**—A taxon sampling scheme was designed based on a preliminary analysis of 457 nuc-lsu sequences representing 40 genera and 247 species (Binder & Hibbett 2006), including 42 unnamed species. The nuc-lsu sequences were aligned manually using the PAUP editor and analyzed in the RAxML Blackbox server using the default settings with maximum likelihood (ML) optimization (<http://phylobench.vital-it.ch/raxml-bb/>; Stamatakis et al. 2008; Swofford 2002). Based on the resulting phylogenetic tree (not shown) a sampling scheme was designed, including 93 individuals for which genomic DNA was available, that represents, as broadly as possible, the phylogenetic diversity of the Boletineae as represented in that tree. Amplification of tef1 and RPB1 genes was attempted using the 93 selected gDNAs. Forty-seven new tef1, forty new RPB1 sequences, and seven new nuc-lsu sequences were generated. An additional 28 previously unpublished nuc-lsu sequences were used.

Single-gene analyses were conducted to assess variability of the intron regions in tef1 and RPB1, and conflict among individual genes using bootstrapped RAxML searches (results not shown). The intron regions of tef1 and RPB1 were analyzed by eye and deemed conserved enough to warrant inclusion in the analyses, and no well-supported conflict was detected between topologies of the three genes. The nuc-lsu, tef1, and RPB1 genes were then combined into two multi-gene datasets: a 'core' dataset containing 48 species, each of which is represented by all three genes, and an 'extended core' dataset, containing all of the sequences from the core dataset, plus 31 species represented by nuc-lsu and tef1 sequences. Finally, a constrained analysis of 370 nuc-lsu sequences (a subset of those used in the preliminary analysis), containing 249 sequences publicly available from GenBank and 96 unpublished sequences, was conducted using the ML topology from the extended core dataset as the backbone constraint because the extended core dataset contains more species and provided better resolution.

### PCR amplification and sequencing

PCR primer pair EF1-983F—EF1-2218R (Rehner & Buckley 2005) was used for amplification of the tef1 fragment (approx 900–1200 bp). A new Boletineae specific (with the exception of Chalciporus species, which have a divergent sequence at this region) external, forward RPB1 primer, RPB1-Bf 5'-GAATGY ATATGYGTWAACGTGTTGG-3' was designed for this study. This primer was designed to bind upstream of intron A, as an alternative to RPB1-Af. RPB1-Bf was paired with RPB1-Cr (Matheny et al. 2002) for amplification of the RPB1 fragment (approx 900–1200 bp).

A touchdown PCR protocol was used to amplify tef1 and RPB1. The following protocols are for tef1: (1) initial denaturation 94 °C for 2 min, (2) denaturation 94 °C for 40 s, (3) 60 °C for 40 s, minus 1 °C per cycle, (4) 72 °C for 1 min, (5) repeat from step 2 for nine cycles, (6) 94 °C for 45 s, (7) 50 °C for 1 min 10 s, (8) 72 °C for 1 min 30 s, (9) repeat from step 6 for 36 cycles, (10) 72 °C for 10 min. For RPB1 PCR protocol see Justo & Hibbett (2011).

● – Feature present in at least one species in genus.

○ – Feature absent in all species.

? – unknown.

\* Stipe is highly reduced, nearly not present.

\*\* Veil is present in the form of a gelatinous mass that disappears with age, and is not considered to be a veil by all mycologists.

For sequencing, two additional internal *tef1* primers; EF1-1577F and EF1-1567F, and a different terminal reverse primer, EF1-2212R were used (Rehner & Buckley 2005). An additional four internal primers were used for RPB1: RPB1-2F, RPB1-2.1F, RPB1-2.2F, and RPB1-2.1R (Frøslev et al. 2005; Binder et al. 2010).

Using primer pair LR0R–LR7, (Vilgalys & Hester 1990), seven nuc-lsu sequences were generated .The following PCR protocol was used: (1) initial denaturation 95 °C for 2 min, (2) denaturation at 94 °C for 45 s, (3) annealing at 50 °C for 1 min 10 s, (4) extension at 72 °C for 2 min, (5) repeat from step 2 for 34 cycles, (6) 72 °C for 10 min (Binder et al. 2010). Sequencing was done using the same PCR primers and two additional internal primers, LR3R and LR5 (Vilgalys & Hester 1990).

All sequencing was done using the BigDye 3.1 terminator sequencing chemistry (Applied Biosystems, Foster City, California) on an Applied Biosystems 3130 Genetic Analyzer. The raw

sequences were processed using Sequencher™ 4.7 (GeneCodes, Ann Arbor, Michigan). Expected fragment length and alternative primers for all genes can be found at <[http://www.clarku.edu/faculty/dhimbett/Protocols\\_Folder/Primers/Primers.htm](http://www.clarku.edu/faculty/dhimbett/Protocols_Folder/Primers/Primers.htm)>.

#### Sequence alignment and phylogenetic analysis

Sequences were separately aligned by gene using MAFFT (<http://mafft.cbrc.jp/alignment/server/>; Katoh et al. 2002). All genes were aligned using the Q-INS-i strategy, and were then manually optimized using MacClade 4.08 (<http://macclade.org/>; Maddison & Maddison 1992). The core and extended core datasets were created by concatenating the single gene datasets using MacClade.

All alignments were analyzed using RAxML (Stamatakis et al. 2008) for ML analyses, PAUP\*4.0.b10 (Swofford 2002) for maximum parsimony (MP), and PhyloBayes (Lartillot 2004;

Lartillot & Philippe 2006; Lartillot et al. 2007) for Bayesian analysis (BY). Alignments have been deposited in TreeBase (# 14219).

ML analyses were run using ML optimization, 1000 bootstrap (BS) replicates, and the GTRCAT and gamma model. MP analyses were performed using parameters published by Justo & Hibbett (2011). BY analysis was done with four MCMC chains using the CAT-GTR settings. BY analyses was run until convergence, indicated by a max difference output of the 'bpcomp' command of less than 0.1. Nodes were considered well supported if the BS value was greater than 70 % for ML and MP, and posterior probability (PP) for BY was greater than 0.95.

For the constrained analysis, 380 nuc-lsu sequences were aligned using the G-INS-i strategy on MAFFT server (<http://mafft.cbrc.jp/alignment/server/>). Ten duplicate sequences were removed, resulting in a 370 taxon matrix. The alignment was analyzed using the extended dataset ML tree topology as the backbone. Constrained analysis was performed using RAxML with ML optimization, 500 BS replicates, and the GTRCAT and gamma model.

---

## Results

### DNA extractions, PCR and sequencing

Tef1, RPB1, and *nuc-lsu* had 68 %, 42 %, and 100 % success rate for sequencing respectively. The low success rate for RPB1 amplification is probably due to primer mismatches.

## *Alignment and phylogenetic analysis*

See Table 3 for technical output of the nuc-lsu, tef1, and RPB1 ML core and extended analyses, the core and extended MP analyses, and the constrained analysis. Following single-gene analyses to assess conflict, the core nuc-lsu, tef1, and RPB1 alignments were merged, as were the extended nuc-lsu, tef1, and RPB1 datasets. The majority of nuc-lsu sequences were generated with the primer set LR0R–LR5; however, some nuc-lsu sequences used were generated using LR0R–LR7 resulting in longer sequences, by approximately 800 bp. These longer sequences were left untrimmed. Thus, the proportion

of gaps and undetermined characters in the nuc-lsu dataset is artificially inflated due to the use of different primer pairs.

For the BY analyses, maximum differences in split frequency between runs dropped to zero after approximately 51 000 cycles for the core dataset and 27 000 for the extended dataset, and the chains were then stopped. The chains for each dataset were analyzed with the readpb program, removing 10 % of the samples as burn-in. A total of 91 789 trees were used to estimate PPs for the core dataset, and 49 367 trees for the extended dataset (Table 4).

## Taxonomy

*Boletus separans* Peck, Bull. Buffalo Soc. Nat. Sci. 1: 59 (1873).

Synonyms: *Boletus edulis* spp. *separans* (Peck) Singer, Amer. Midl. Nat. 37: 26 (1947).

*B. edulis* f. *separans* (Peck) Vassilkov, Belyi Grib: 15 (1966).

*Xanthoconium separans* (Peck) Halling & Both, Bull. Buffalo Soc. Nat. Sci. 36: 240 (1998).

TYPE: New York. Greenbush, August 1872, C.H. Peck (NYS).

MycoBank #: 226550.

*Boletus subalpinus* (Trappe & Thiers) M. Nuhn, Manfr. Binder, A. F. S. Taylor, Halling, Hibbett, *comb. nov.*

Basionym: *Gastroboletus subalpinus* Trappe & Thiers Brittonia 21: 245 (1969).

TYPE: Oregon. Hood River Co., Cloud Gap, Trappe 607 (Holotype: OSC).

MycoBank #: 804290.

*Boletus semigastroides* M. Nuhn, Manfr. Binder, A. F. S. Taylor, Halling, Hibbett, *nom. nov.* for *Secotium areolatum* G. Cunn., New Zealand J. Sci. Technol. 23: 172B (1942), non *Boletus areolatus* Berkeley, Hooker's J. Bot. Kew Gard. Misc. 4: 138 (1852).

Synonym: *Notholepiota areolata* (G. Cunn.) E. Horak, New Zealand J. Bot. 9: 479 (1971).

TYPE: New Zealand. Auckland, Swanson, J. Dingley, IV. 1943 (Holotype: PDD 4595).

MycoBank #: 804291.

## Discussion

### Overview of phylogenetic relationships in Boletineae

In both the three-gene core and extended datasets, the Boletineae and Boletaceae are upheld with maximum supported values in all analyses (BS = 100 %, MP = 100 %, PP = 1.0, reported as [BS/MP/PP] hereafter), but the backbone of the

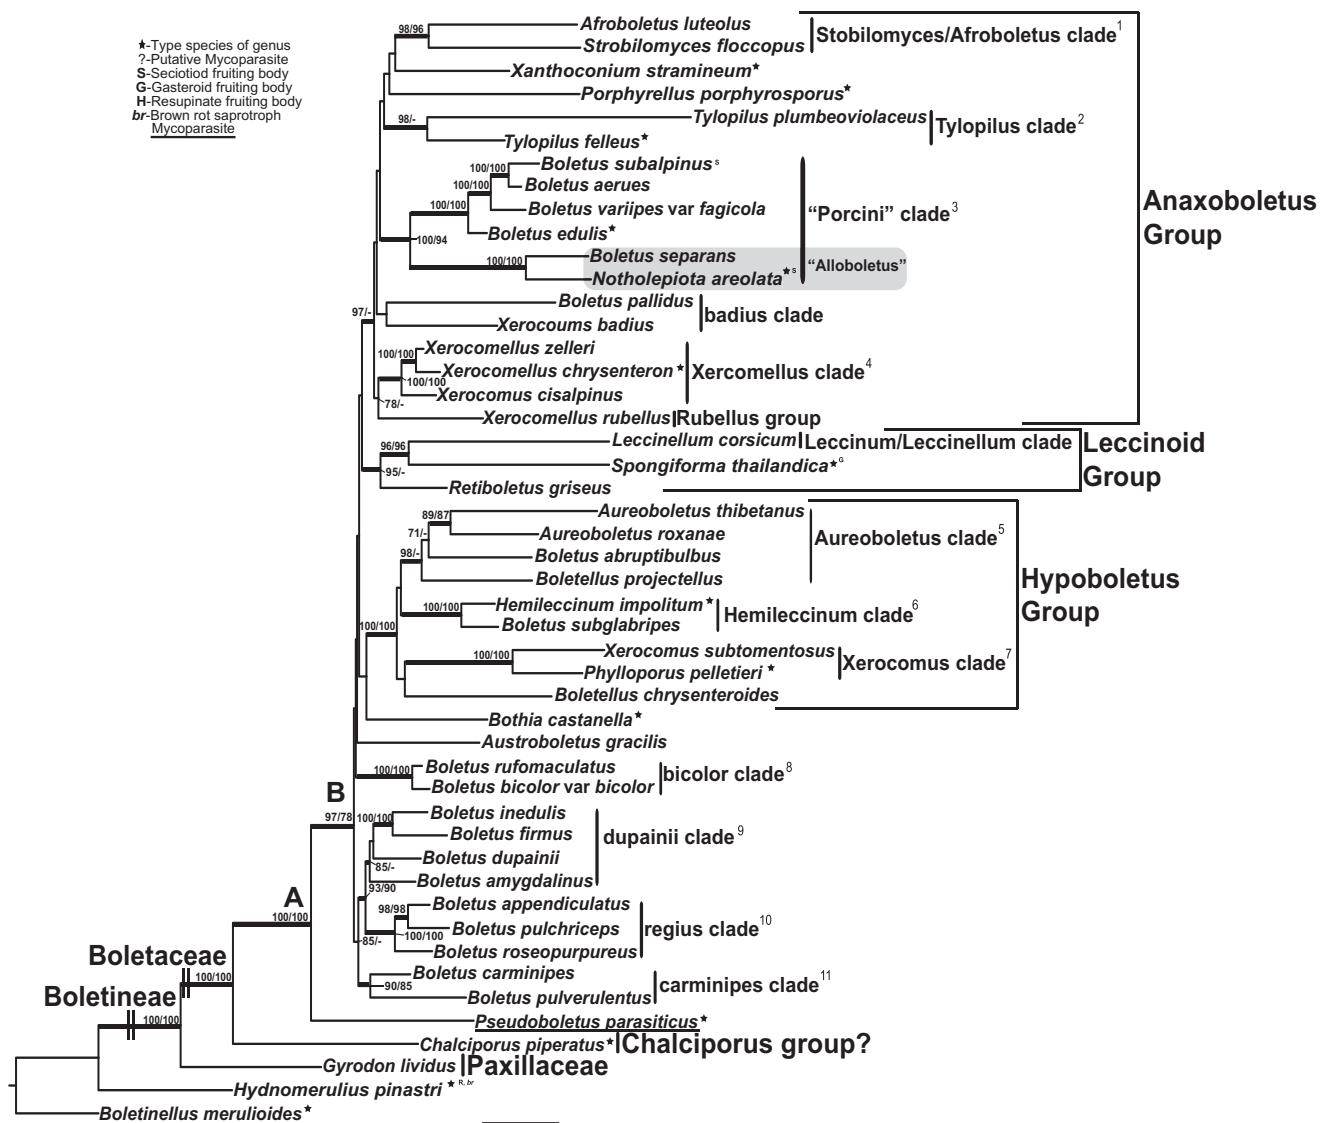

**Table 4 – Alignment Information from ML and MP analyses.**

Alignment	ML			MP			
	Positions	Alignment patterns	% Gaps and undetermined characters	Characters	Constant characters	Uninformative characters	Informative characters
nuc-lsu, core	1537	482	35	N/A	N/A	N/A	N/A

Three gene core	N/A	N/A	N/A	4349	2434	543	1327
Three gene extended	N/A	N/A	N/A	4759	2732	558	1469

*Boletaceae* remains poorly resolved. Nonetheless, there are eleven strongly supported, named clades shared in both the three-gene core and extended, and an additional seven supported, named clades in the three-gene extended (see Figs 1 and 2 for clades; clades 1–11 are shared, clades 12–18 are only in the three-gene extended analysis). The named, supported clades may provide the basis for an eventual generic level reclassification of the *Boletaceae*. The major groups, which we informally label as *anaxoboletus*, *leccinoid*, *hypoboletus*, *bicolor*, *dupainii*, *regius*, *carminipes*, *chalciporus*, and *Paxillaceae* are all upheld by at least two of the three analysis methods (above 70 % for BS and MP, and 0.95 for PP) in the three-gene core and extended phylogenies. However, two groups, *chalciporus* and *Paxillaceae*, are represented by single

taxa in the three-gene core analysis. The overall tree topology is identical for the core and extended analyses. Eleven strongly supported sub-groups within the anaxoboletus, leccinoid, and hypoboletus groups are discussed below. Except for the *Paxillaceae*, group names do not correspond to formal taxa. Group names were designated based on the most inclusive clade with strong support and are only meant to facilitate discussion.

The anaxoboletus group unites the genera *Afroboletus*, *Boletus*, *Gastroboletus*, *Notholepiota*, *Porphyrellus*, *Tylopilus*, *Strobilomyces*, *Xanthoconium*, *Xerocomellus*, and species referred to as *Xerocomus* but shown to not be closely related to *Xerocomus subtomentosus*, the type species of *Xerocomus*. *Boletus*, *Gastroboletus*, *Notholepiota*, and *Xanthoconium* found in anaxoboletus

**Fig 1 – Phylogenetic relationships of the Boletineae inferred from *nuc-ls*, *tef1*, and *RPB1* using RAxML, PhyloBayes, and PAUP\*. This is referred to as the three-gene core analysis in the text. The tree topology corresponds to the optimal ML tree. Support values  $\geq 70\%$  BS for ML and MP are displayed [ML/MP], and PPs  $\geq 0.95\%$  are depicted by bold branches. Groups and clades that were recovered in the analysis are indicated, and three taxonomic ranks are indicated: Boletineae, Boletaceae and Paxillaceae. Nodes indicated by A and B indicate the most inclusive and second most inclusive clades that lack a formal taxonomic rank, respectively. Numbered clades 1–11 are the clades the core analysis shares with the extended analysis.**

are members of the 'porcini' group as defined by Dentinger et al. (2010) and is equivalent to Singer's *Boletus* section *Boletus* (Singer 1986) containing the type species: *Boletus edulis*. The leccinoid group unites the genera *Leccinellum*, *Leccinum*, *Spongiforma*, and *Retiboletus*. The hypoboletus group contains members of *Aureoboletus*, *Boletellus*, *Boletus* (non-porcini), *Hemileccinum*, *Phylloporus*, and *Xerocomus* (the clade with the type species). The relationship between these three lineages is unresolved. *Chalciporus* spp. and *Buchwaldoboletus lignicola* are supported as a clade, designated chalciporus group.

Two other nodes receive support, node A and node B (see Figs 1 and 2). Node A supports the sister group relationship between the chalciporus group and all other members of the Boletaceae (see Figs 1 and 2), and node B supports *Pseudoboletus parasiticus* as the sister group of the non-chalciporus group Boletaceae. All other nodes with support correspond to groups that could be considered genera.

Diverse morphology-based generic concepts have been proposed in the Boletineae, with most genera containing a small or moderate ( $\leq 50$ ) number of species (Pilát 1969; Smith & Thiers 1971; Singer 1986; Binder & Besl 2000; Binder & Bresinsky 2002b; Binder & Hibbett 2006; Šutara 2008; Halling et al. 2012a, b). Twenty-three genera are included in the core analysis, representing roughly half of the total genera of the Boletineae that have molecular data available, and 28 genera are included in the extended analysis. In the extended analysis, the following genera are recovered as monophyletic: *Strobilomyces*, *Leccinum*, *Leccinellum*, *Royoungia*, *Chalciporus*, and *Paxillus*. However, the following genera are not monophyletic using current generic concepts: *Aureoboletus*, *Boletellus*, *Boletus*, *Xanthoconium*, *Xerocomellus*, and *Xerocomus*.

The most difficult taxonomic issue facing boletologists concerns the genus *Boletus*. The type species of *Boletus*, *B. edulis*, is nested in the strongly supported 'porcini clade', which is part of the anaxoboletus group, but many other species of 'Boletus' are distributed among the distantly-related bicolor, dupainii, regius, and carminipes clades (Fig 2). Members of the 'porcini,' bicolor, dupainii, regius, and carminipes clades all share smooth spores, a spore print colour reported as some hue of olive brown, tube trama of the boletoid type, and other characters (Smith & Thiers 1971; Singer 1986; Bessette et al. 2000; Ladurner & Simonini 2003; Muñoz 2005; Dentinger et al. 2010). However, the bicolor, dupainii, regius, and carminipes clade species are distinguished from the 'porcini' clade by the lack of a white pore surface when young and absence of the 'stuffed' pore characteristic (Dentinger et al. 2010). The present study lacks the necessary sampling to attempt to resolve the *Boletus* spp. that are not members of *Boletus* s.str., which may represent additional independent clades.

While the need for a reclassification of *Boletus* has been evident for some time (Binder & Hibbett 2006), certain infrageneric taxa within *Boletus* have been shown to be problematical. For example, *Boletus* sect. *Subtomentosus* sensu Smith & Thiers (1971) is represented by members of the carminipes clade and *Boletus pallidus*, this latter appears in the distantly related badius clade of the anaxoboletus group (Fig 2). Similarly, species of *Boletus* sect. *Calopodes* sensu Singer (1986) are distributed across the carminipes clade and the regius clade (Fig 2). Even some putative species have proven to be polyphyletic. Specifically, *Boletus bicolor* var. *bicolor* and *B. bicolor* var.

*borealis* sensu Smith & Thiers (1971) occur in two separate groups, the bicolor and carminipes clades, respectively and are not, based on our results, the same species.

### Ecological diversity in Boletineae

The great majority of the species of the Boletineae are ectomycorrhizal (ECM) (Binder & Hibbett 2006; Tedersoo et al. 2010). However, *Pseudoboletus parasiticus* and species of the Chalciporus group (*Chalciporus piperatus* and *Buchwaldoboletus lignicola*) appear to be mycoparasites (Modess 1941; Godbout & Fortin 1985; Yamada & Katsuya 1995; Kasuya & Igarashi 1996; Höglberg et al. 1999; Taylor et al. 2003; Zeller et al. 2007; Tedersoo et al. 2010). *Pseudoboletus parasiticus*, which produces its fruiting bodies on those of its host, *Scleroderma citrinum* (Sclerodermatinae), is well characterized as a mycoparasite, but evidence on the nutritional mode of *Chalciporus piperatus* is not as clear-cut.

*Chalciporus piperatus* was originally considered to be ECM, but several synthesis attempts failed to show formation of ECM with tree species *in vitro* (Modess 1941; Godbout & Fortin 1985; Yamada & Katsuya 1995; Kasuya & Igarashi 1996; Zeller et al. 2007). Garrido (1988) reported successful ECM synthesis using *C. piperatus*, but Tedersoo et al. (2010) urged caution, stating that the illustrations of Garrido (1988) do not resemble true ECM hyphal formations. Additionally, isotopic analysis suggested that *C. piperatus* may be saprotrophic (Höglberg et al. 1999; Taylor et al. 2003). However, isotopic values for saprotrophic species, especially leaf litter decayers, and some mycoparasites can overlap with isotopic values for ECM species (Hobbie et al. 1999; Höglberg et al. 1999; Hobbie et al. 2001).

Ecological observations suggest a mycoparasitic nutritional mode for *C. piperatus*, which has been found in association with its putative host, *Amanita muscaria* (Agaricales), in New Zealand and Australia (Robinson 2010). *Pinus radiata* is a non-native species in New Zealand that forms ECM with *A. muscaria*, which is thought to have been introduced along with *P. radiata*. *Amanita muscaria* has made a host jump onto the native *Nothofagus*, and *C. piperatus* has been observed fruiting in proximity to *A. muscaria* associated with *Nothofagus*, implying that it followed *A. muscaria*'s mycorrhizal host shift (Tedersoo et al. 2010; Dunk et al. 2012).

*Buchwaldoboletus lignicola*, which is the sister taxon of *Chalciporus*, also appears to be mycoparasitic. Fig 3 depicts the results of a confrontation experiment in which the hyphae of *B. lignicola* can be seen wrapping around hyphae of *Phaeolus schweinitzii*, a known brown-rot tree pathogen. *Buchwaldoboletus lignicola* is associated with *P. schweinitzii* in the field and appears to be dependent on the latter for growth (Szczepka & Sokól 1984), which contradicts suggestions that it is saprotrophic (Pantidou 1962; Pilát 1965). Collectively, the confrontation analysis and association with *P. schweinitzii* of *B. lignicola*, and the isotopic and ecological evidence for *C. piperatus* support a mycoparasitic nutritional mode for some members of the Chalciporus group (Taylor et al. 2003; Zeller et al. 2007). Because the Chalciporus group and *P. parasiticus* are nested within the Boletineae (Figs 1 and 2), the genera may represent parallel shifts in nutritional mode from the ECM nutritional mode shared by members of the Paxillaceae and all of the species above node B (Figs 1 and 2).

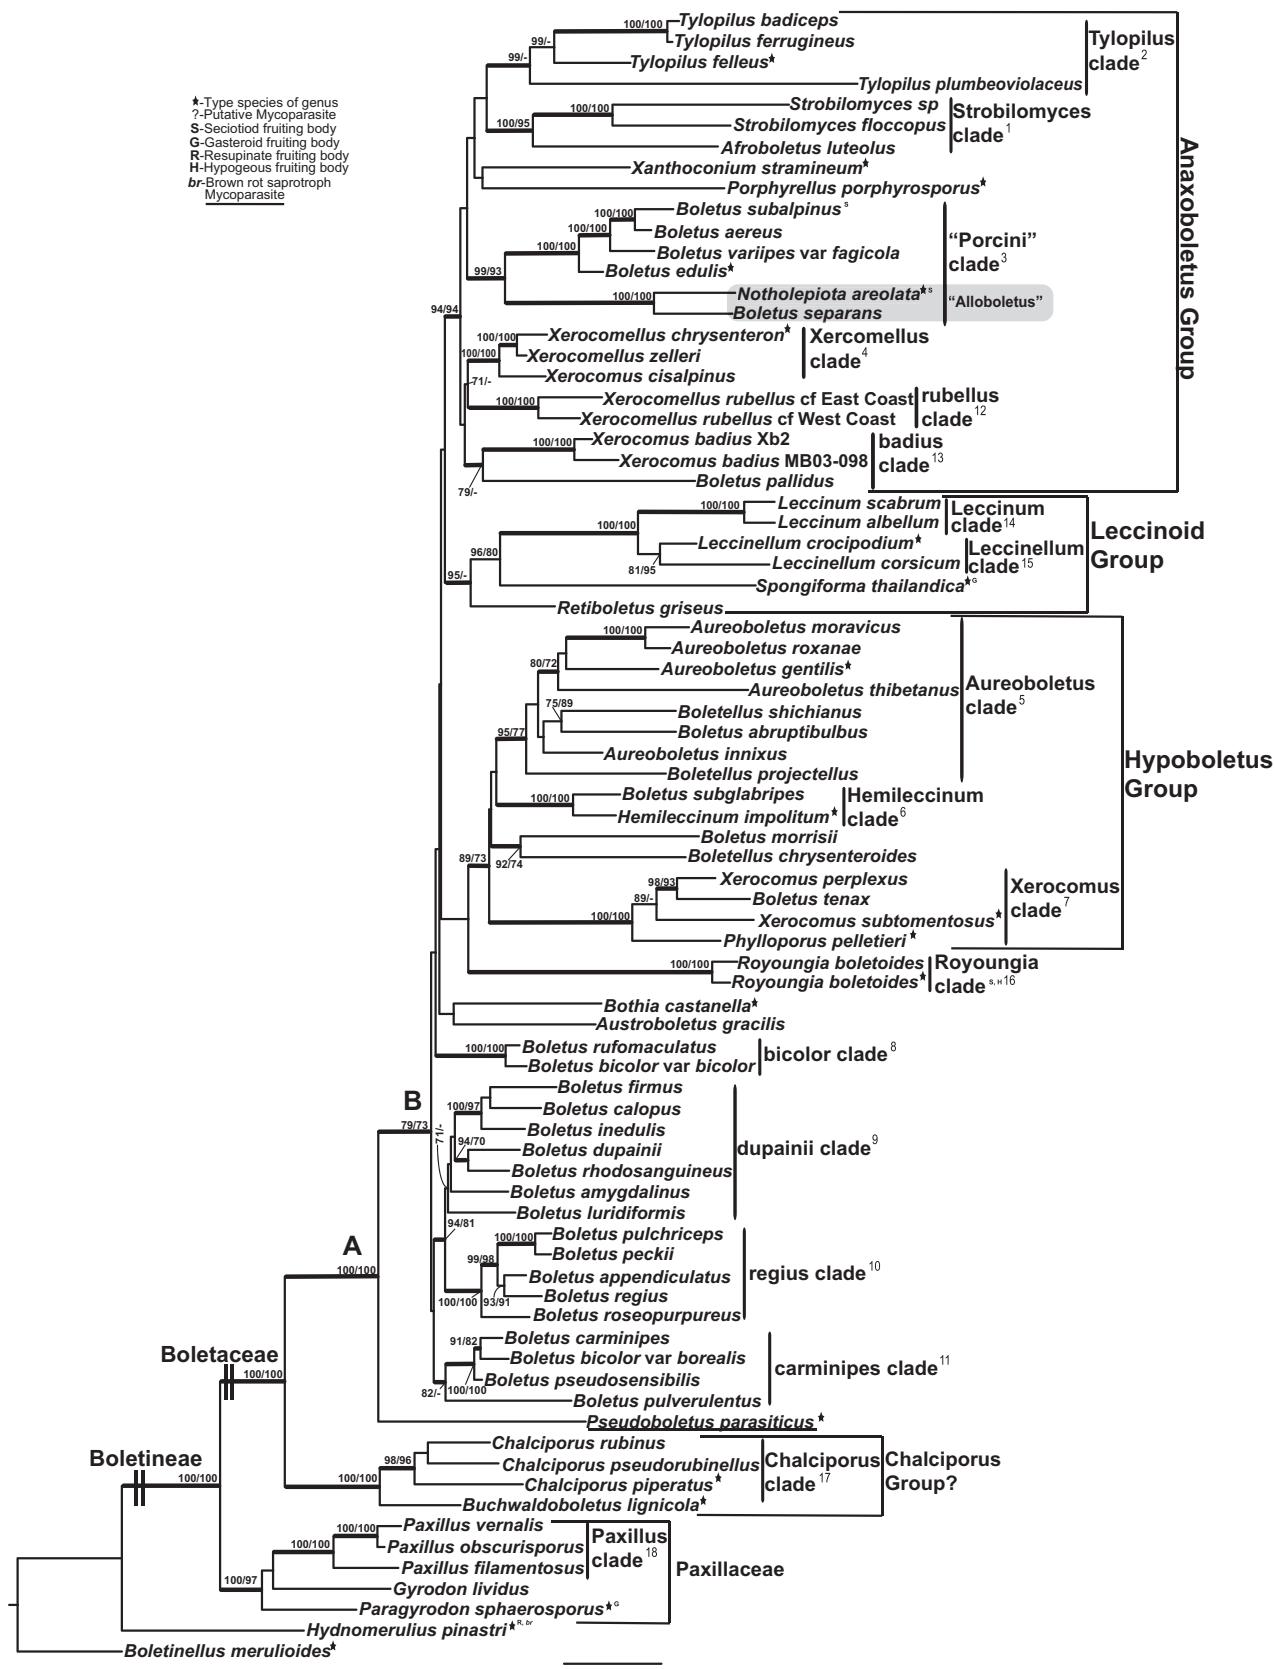

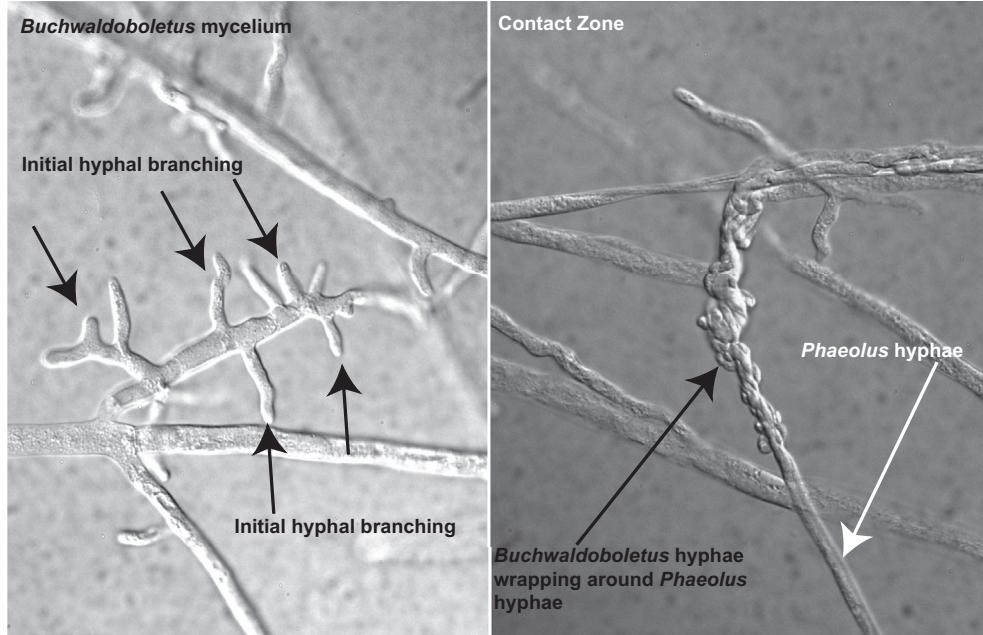

Fig 2 – Phylogenetic relationships of the Boletineae inferred from nuc-lsu, tef1, and RPB1 using RAxML, PhyloBayes, and PAUP; all taxa have nuc-lsu and tef1, but not all taxa have RPB1. This is referred to as the three-gene extended analysis in the text. The tree topology corresponds to the optimal ML tree. Support values  $\geq 70\%$  BS for ML and MP are displayed [ML/MP], and PPs  $\geq 0.95\%$  are depicted by bold branches. Groups and clades that were recovered in the analysis are indicated, and three

### Confrontation test between *Buchwaldoboletus* and *Phaeolus*

**Fig 3 – Confrontation analysis between the hyphae of *Buchwaldoboletus lignicola* and *Phaeolus schweinitzii*.** Initial hyphal branching of *Buchwaldoboletus lignicola* is seen in the image on the left and indicated by blue arrows. In the image on the right, the black arrow indicates the *P. schweinitzii* hypha and where the hyphae of *B. lignicola* are wrapping around a hyphal strand of *P. schweinitzii*, indicated by a white arrow. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

#### Clade-by-clade discussion of Boletineae

Because the topologies of the three-gene core and extended phylogenies are congruent, the following discussion refers to the more inclusive extended phylogeny. Discussion of the systematic and morphological features of the clades is confined to the taxa presented in Fig 2. The congruent Fig 2 clades in the constrained analysis (Sup. Fig 1) are discussed only when well-supported or otherwise noteworthy, but due to the lack of support for nearly all nodes on the constrained tree (Sup. Fig 1), morphological and systematic features are generally not discussed. For complete contents of the constrained analysis clades see Table 5 and Sup. Fig 1 for tree topology. *anaxoboletus* group [94/94/0.99]—*Anaxoboletus* comprises six clades: *Tylopilus*, *Strobilomyces* (including *Afroboletus luteolus*), *Boletus* sensu stricto, *Xerocomellus*, ‘*rubellus*’, and ‘*badius*’ and two unresolved genera typified by *Xanthoconium stramineum* and *Porphyrellus porphyrosporus*. The relationships between clades are not resolved.

*Tylopilus* clade [99/-/1.0]—The *Tylopilus* species in the extended analysis are recovered as monophyletic, with a placement within the tree that is similar to that in Dentinger et al. (2010). Li et al. (2011) reported *Tylopilus* as polyphyletic

considering the placement of *Tylopilus chromapes* outside the clade containing the type species, *Tylopilus felleus*. Recently, two new genera, *Harrya* and *Australopilus*, have been described to accommodate the *T. chromapes* complex (Halling et al. 2012b). Despite these recent works, there still remain species called *Tylopilus* that are not supported as members of *Tylopilus* s.str. or lack enough molecular and morphological data to place in a different genus or erect a new genus; e.g. *Tylopilus alboater*, *Tylopilus atronicotianus*, *Tylopilus badiceps*, *Tylopilus rhoadsiae*, *Tylopilus variobrunneus*, *Tylopilus virens* (see Sup. Fig 1; Binder & Hibbett 2006). The *Tylopilus* clade containing *T. felleus* in Li et al. (2011) corresponds to this study’s *Tylopilus* clade. The least inclusive clade containing all the species from the three-gene analysis receives no support in the constrained analysis; nevertheless it contains only species placed in *Tylopilus*.

The traditional morphological concept of *Tylopilus* is that of smooth spored species, with or without a reticulum on the stipe, a spore print of pinkish to various brown hues, and a pore surface that is frequently white when young and turns pink, yellow, brown, grey or black with age (Bessette et al. 2000; Singer 1986; Smith & Thiers 1971; Watling 2008). The variable pore surface colour with age is one of the characters that

taxonomic ranks are indicated: Boletineae, Boletaceae and Paxillaceae. Nodes indicated by A and B indicate the most inclusive and second most inclusive clades that lack a formal taxonomic rank, respectively. Clade numbers 1–11 represent the clades the extended analysis shares with the core analysis, numbers 12–18 represent clades in the extended analysis only.

<sup>a</sup> Type species for genus.

separate *Tylopilus* from *Boletus* s.str. The context is often bitter tasting in the type, *T. felleus* and a few other species, but not everyone is able to detect this (personal experience; Aurora 1986).

The species in the three-gene extended *Tylopilus* clade are members of either the stirps *felleus* or *indecisus* of Smith and Thiers, and Singer's *Tylopilus* subsections *Tylopilus* or *Oxydables* (Singer 1986; Smith & Thiers 1971). The morphological concept of *Tylopilus* circumscribes a non-monophyletic grouping of species, despite recent works that have removed several species previously assigned to either *Boletus*, *Tylopilus* or *Leccinum*, and created the new genera *Australopilus*, *Harrya*, and *Sutorius* (Halling et al. 2012a, b). Smith and Thiers's (1971) morphological concept of the stirps *felleus* and *indecisus* is species that have smooth spores that are pinkish to vinaceous in print, pileus that is violaceous, vinaceous-brown or tan-ish, with a reticulate stipe. Singer's (1986) concept of the *Tylopilus* sections *Tylopilus* and *Oxydables* encompasses smooth spored species, with a spore print that is pinkish to a grey-brown colour, a stipe that is typically reticulated, and a pileus colour that is highly similar to Smith and Thiers's (1971) concept. Further sampling is needed to know if these stirps and sections are sufficient to circumscribe the members of the least inclusive clade containing *T. felleus*.

*Strobilomyces* clade [100/95/1.0]—This placement of the *Strobilomyces* clade in relation to other Boletineae genera is novel. *Afroboletus luteolus* receives strong support as the sister group of *Strobilomyces* [100/95/1.0]. *Afroboletus* was first recognized as unique by Singer (1945) and placed in *Strobilomyces* section *Pterospori*; the only other section in *Strobilomyces* besides section *Strobilomyces*. Later, Pegler & Young (1981) recognized *Afroboletus* as a distinct genus based on unique spore morphology. As with *Tylopilus*, the clade containing all of the three-gene *Strobilomyces* clade members (including *Afroboletus*) receives no support in the constrained analysis. However, a clade containing the three-gene *Strobilomyces* spp., and not *Afroboletus luteolus*, receives 99 BS support in the constrained analysis and includes *S. dryophilus*, a different *S. floccopus* exemplar and a different *Strobilomyces* sp. exemplar.

The species of the *Strobilomyces* clade are morphologically distinct, with a veil and coarsely fibrillose to conspicuously scaly pileus with scales turning grey to black (Smith & Thiers 1971). *Strobilomyces* spores are globose, with reticulate or variously echinate to cristate ornamentation (see Table 2), never having longitudinal costae and a dark rusty brown to blackish brown spore print (Smith & Thiers 1971; Pegler & Young 1981). Pegler & Young (1981) moved members of Singer's section *Pterospori* to *Afroboletus* based on spore shape and ornamentation, subglobose to ellipsoid, longitudinally costate, with a basal thickened rim (around apiculus), and the restriction of these species to Africa. Because recent works have described both morphological affinities and clades containing a genus or closely related genera with species from multiple continents, e.g. *Sutorius* spp., *Harrya chromapes* and *H. chromapes* like species and *T. ballouii*, it seems plausible that *Afroboletus* may be restricted to Africa and could either be the sister genus of *Strobilomyces* or merely a geographically isolated *Strobilomyces* lineage (Wolfe & Bouger 1993; Osmundson & Halling 2010; Halling et al. 2012a, b, 2008).

*Xanthoconium stramineum* and *Porphyrellus porphyrosporus*—Both are type species of their respective genera, are strongly supported as members of the anaxoboletus group, but their placement within the anaxoboletus group in respect to the other members is not resolved. This is in conflict with the topology presented by Hosen et al. (2012), but there is no support for nodes along the backbone of that phylogeny either.

In the constrained analysis, *P. porphyrosporus* forms a clade with 99 % BS support with five other *Porphyrellus* taxa. *Xanthoconium stramineum* forms a clade with 80 % BS containing four other *Xanthoconium* taxa and *Tylopilus badiceps*, which may be misidentified. The placement of the clade containing *X. stramineum* and *P. porphyrosporus* in the three-gene analysis is topologically similar to the results of other studies (Desjardin et al. 2008, 2009; Dentinger et al. 2010).

Morphologically, *Xanthoconium* was separated from *Boletus* based on unique golden yellow colour of the spores under microscopic view and in deposit, and the absence of certain pigments, though Singer neither mentions nor provides a citation for these different pigments (Singer 1944, 1947, 1986). Furthermore, Singer (1986) separated *Xanthoconium* from *Tylopilus* based on the colour of the spores, the unchanging white, mild context, and the non-reticulate, non-pustulate-floccose stipe. Smith and Thiers's (1971) concept did not recognize *Xanthoconium* as unique, instead placing the species in *Boletus* subsection *Versicolores* strips *Affinis*.

Later works included reticulate species in an expanded concept of *Xanthoconium* (Smith 1973; Wolfe 1987; Halling & Both 1998). Singer (1944) originally placed *Xanthoconium stramineum* and *X. affine* in *Xanthoconium*, both of which were described as having a glabrous stipe, but other authors have reported reticulation at the apex of the stipe of these two species (Wolfe 1987, 1988, 1989; Halling & Both 1998; Bessette et al. 2000). Halling & Both (1998) placed *Boletus separans* in the genus, partially based on previous inclusions of reticulate species in the genus. Molecular data does not support the inclusion of *B. separans* in *Xanthoconium* (see Figs 1 and 2). *Xanthoconium separans* is described as reticulate on at least the upper portion of the stipe or finely reticulate as in *Boletus edulis*, while all members of *Xanthoconium* with molecular support, *X. stramineum* and *X. affine* in this study and *Xanthoconium purpureum* (=*Boletus purpureofuscus* H.V. Smith & A.H. Smith) in Dentinger et al. (2010), are described as glabrous or reticulate only at the very apex of the stipe (Smith & Thiers 1971; Singer 1986; Wolfe 1987, 1988; Bessette et al. 2000). Additionally, *X. separans* shares the 'stuffed' pore feature found in all non-secotoid members of the 'porcini' group (Smith & Thiers 1971; Singer 1986; Dentinger et al. 2010).

'porcini' Clade [99/93/1.0]—This group is recovered with similar placement in the Boletaceae as reported by Dentinger et al. (2010) and Li et al. (2011). Following the terminology outlined by Dentinger et al. (2010), the clade containing *Boletus edulis* but not *Xanthoconium separans* is *Boletus sensu stricto*, and the clade containing *X. separans* but not *B. edulis* is 'alloboletus.' *Notholepiota areolata* is placed in the 'porcini' clade for the first time. *Notholepiota areolata* was originally described as a secotoid member of the Agaricaceae by Horak (1971), but was later shown to have affinities with the Boletaceae (Vellinga 2004). *Xanthoconium separans* was previously placed

in *Boletus* and removed based on morphological characters, but is not closely related to the type of *Xanthoconium* (see Figs 1 and 2; Halling & Both 1998).

An equivalent ‘porcini’ clade is not supported in the constrained analysis, but the two major clades inside the ‘porcini’ are supported in the constrained analysis, with 89 % BS for *Boletus* s.str. clade and 95 % BS for the ‘alloboletus’ clade, including *N. areolata*.

Morphologically, *Boletus* s.str. has been united by a variety of characters: white (or pale yellow) unchanging context tissue that is mild tasting, smooth spores that are yellow-brown or olive-brown in deposit, stipe with enlarged base and reticulum, a hyphal mat (cheilocystidia) that covers the tubes of immature specimens, leading to the ‘plugged’ or ‘stuffed’ pore feature (Coker & Beers 1943; Smith & Thiers 1971; Singer 1986; Dentinger et al. 2010). The ‘stuffed’ pore feature has been reported in species that are distantly related to *Boletus* s.str., including a *Phlebopus* sp. (Sclerodermatinae) (Singer 1986; Miller Jr et al. 2000) and is mimicked in *Xanthoconium* sensu Singer by compressed pore mouths in young specimens (Singer 1986). Despite variations in morphological features, a combination of white context, reticulated stipe, smooth spores, pore surface that is white or nearly white when young, basal mycelium that is white, and a ‘stuffed’ pore appearance due to a mycelium layer growing over the pore surface appear unique to the ‘porcini’ clade (Coker & Beers 1943; Smith & Thiers 1971; Singer 1986; Dentinger et al. 2010). Dentinger et al. (2010) provide an in-depth overview of morphological traits in the ‘porcini’ group.

*Xerocomellus* clade [100/100/1.0]—The placement of the *Xerocomellus* clade in the ‘anaxoboletus’ is mirrored in Li et al. (2011), though there is no support for a group corresponding to the ‘anaxoboletus’ in Li et al. (2011). The *Xerocomellus* clade contains the type species, *Xerocomellus chrysenteron*, and the division between *Xerocomellus* and *Xerocomus subtomentosus* based on morphological features is supported by a host–parasite study of the group and the phylogeny in Figs 1 and 2 (Douhan & Rizzo 2003; Šutara 2008). Further, Peintner et al. (2003) support the division of the *Xerocomellus* and ‘rubellus’ clades. The *Xerocomus*/*Xerocomellus* containing clades (*Xerocomellus*, ‘rubellus,’ and ‘badius’) in the ‘anaxoboletus’ group do form an unsupported clade, but are morphologically more similar to each other than other members of the ‘anaxoboletus’.

‘rubellus’ clade [100/100/1.0]—Two ‘rubellus’ specimens were included, one from Eastern USA and one from Western USA. The two specimens form a clade separate from other *Xerocomellus* species. Inclusion of ‘rubellus’ clade in the *Xerocomellus* clade is only supported by 71 % BS support in the ML analysis. Further, the constrained analysis gives 96 % BS support to the clade containing *Xerocomellus rubellus* species.

‘badius’ clade [79/-0.96]—The two *Xerocomus badius* specimens form a clade with *Boletus pallidus*, albeit with weak support. *Boletus pallidus* has been previously recovered in a close relationship to *X. rubellus* (Desjardin et al. 2009). Inside this group the *X. badius* clade receives maximal support. *Xerocomus badius* species form a clade with 100 % BS support in the constrained analysis including one non-*Xerocomellus* species, *Boletus glabellus* 00-194.

Šutara (2008) placed the members of the *Xerocomellus*, ‘badius’, and ‘rubellus’ clades in the genus *Xerocomellus* based on

morphology, however, they form a clade that lacks support in our analyses. Members of these clades were distinguished from *Boletus* based on a hymenophore trama that is intermediate between boletoid and phylloporoid types, a lateral stipe trama that is reduced, no thicker than 30–40 µm and non-gelatinized or absent lateral stipe trama, and spores that are longitudinally striate or smooth, never bacillate (Šutara 2008). *Boletus* has spores that are always smooth, boletoid type hymenophore trama, and lateral stipe stratum that is 60–90 µm thick and often gelatinized (Šutara 2008). The gelatinized trama appears as viscid fluid and/or partially dissolved hyphae surrounding the normal hyphae in the trama.

Additionally, Šutara (2008) separated *Xerocomellus* from *Xerocomus* on the lack of bacillate spores, an intermediate form of hymenophore trama that is never of the phylloporoid trama type, and a pileipellis that is a palisadoderm that typically is heavily encrusted; not a trichoderm with little or no encrustations. See Table 1 for the overview of the morphological features of *Boletus*, *Xerocomellus*, *Xerocomus*.

‘leccinoid’ group [95/-0.99]—There are two clades, *Leccinum* and *Leccinellum*, and two additional species, *Spongiforma thailandica* (type specimen) and *Retiboletus griseus* in this group.

*Leccinum* clade [100/100/1.0]—The clade contains *Leccinum albvellum* and *Leccinum scabrum*. The clade in the constrained analysis containing the two *Leccinum* species receives 100 % BS support and contains 20 extra *Leccinum* taxa. A more inclusive clade in the constrained analysis contains *Octaviania asterosperma* and *Octaviania tasmanica*, but only receives 60 % BS support.

*Leccinellum* clade—The separation of *Leccinellum corsicum* and the type species of *Leccinellum*, *Leccinellum crocipodium*, from the genus *Leccinum* is supported in our analysis [81/95/-], and the clade containing both *Leccinellum* and *Leccinum* receives maximum support in all analysis methods.

Previous studies support the division of *Leccinum* and *Leccinellum*, and the close relationship between the two genera (Binder & Besl 2000; Bresinsky et al. 2003; Dentinger et al. 2010). The branch leading to *Leccinum* and *Leccinellum* in the constrained analysis receives 81 % BS support. There is no support for a *Leccinellum* clade in the constrained analysis.

*Leccinum* and *Leccinellum* species have been circumscribed based on Singer’s (1986) broad classification, or Smith and Thiers’s (1971) more strict classification. Smith & Thiers (1971) used the darkening stipe scabrosities and white context as the defining characteristic of the genus *Leccinum*. Sequence and chemotaxonomic analysis supports a *Leccinum* concept sensu Smith and Thiers over that of Singer’s (Singer 1986; Binder & Besl 2000; Bakker & Noordeloos 2005; Binder & Hibbett 2006). Bresinsky et al. (2003) separated *Leccinellum* from *Leccinum* based on a yellow context, a difference that Smith & Thiers (1971) noted as well.

The placement of *S. thailandica* as sister to the clade containing ‘leccinoid’ species is inconsistent with the studies of Desjardin et al. (2009), Li et al. (2011), and Hosen et al. (2012) where it is sister to *Porphyrellus* and *Strobilomyces*. However, Desjardin et al. (2009) used only nuc-lsu sequence data, which is too conserved to resolve the Boletineae. Despite this, Li et al. (2011) have support for a clade containing *Spongiforma*, *Porphyrellus*, and *Strobilomyces*, and Hosen et al. (2012) have support for a clade containing *Spongiforma* and *Porphyrellus*.

In the constrained analysis *S. thailandica* forms a strongly supported clade [100] with the only other species in the genus, *Spongiforma squarepantsii*. Recently, a new genus, *Borofutus*, was shown to be related to *Spongiforma* (Hosen et al. 2012).

Morphologically, *Spongiforma* species are distinct. The two species known are both gasteroid, appearing like a sponge and are unlike any other members of the Boletales. There is no gross morphological similarity to place *Spongiforma* in the 'leccinoid' clade, or in any other Boletineae clade.

*Retiboletus griseus* is the sister group of the rest of the 'leccinoid' group, which is congruent with previous studies (Dentinger et al. 2010; Lebel et al. 2011; Li et al. 2011). In the constrained analysis *R. griseus* is in a distinct, albeit unsupported, clade that contains all *Retiboletus* species in the analysis and three taxa that are not *Retiboletus* (See Sup. Fig 1).

*Retiboletus* species are highly reticulate along the entire stipe, but morphologically very similar to the classical description of *Boletus*; e.g. smooth spores, olive or brownish spore print (See Table 1; Smith & Thiers 1971; Singer 1986). Retipolides, a unique pigment group, was reported in *Retiboletus/Retiboletus retipes* (Herman 1980), and with additional molecular analysis, the occurrence of this unique pigment provided the description of *Retiboletus* (Binder & Bresinsky 2002b). Not all *Retiboletus* spp. that were placed in the genus with molecular methods have been tested for the occurrence of retipolides, but in all *Retiboletus* species chrysocystidia, which are rare or absent in *Boletus*, are present (Smith & Thiers 1971; Singer 1986; Binder & Bresinsky 2002b; Watling 2008).

While the type species of *Leccinum* is not included in core analyses, the topology of the *Leccinum*, *Leccinellum*, and *Retiboletus* containing clade is identical to the topology of the combined analysis in Dentinger et al. (2010). All members of the 'leccinoid' clade (not including *Spongiforma*) have a boletoid type tube trama, and most have smooth spores. The exception is *S. thailandica* which has rough spores in SEM (Desjardin et al. 2009).

'hypoboletus' group[89/73/0.99]—The 'hypoboletus' group contains four supported clades, three of which we have given designations: *Aureoboletus*, *Hemileccinum*, and *Xerocomus*.

*Aureoboletus* clade [95/77/0.99]—The *Aureoboletus* clade contains eight taxa, five *Aureoboletus* species, two species currently classified in the genus *Boletellus* by some authors, and one *Boletus* species. The type species, *Aureoboletus gentilis* is nested in the clade. The placement of *Boletellus* species within the *Aureoboletus* clade has been reported in previous studies (Binder & Hibbett 2006; Desjardin et al. 2009; Dentinger et al. 2010). Dentinger et al. (2010) included the type species of *Boletellus*, *Boletellus ananas*, which is placed outside of the clade containing the *Aureoboletus* species in their analysis. The phylogeny shown by Li et al. (2011), gives indirect support for this relationship, with *Boletellus mirabilis* and *Boletellus projectellus* as sister group to *Xerocomus illudens* and *X. subtomentosus*, a relationship that has been recovered in the three-gene extended analysis with taxon pruning.

*Aureoboletus* was circumscribed by Pouzar (1957), but Singer's (1986) concept placed all the *Aureoboletus* spp. included in our analysis in the genus *Pulveroboletus* sect. *Auripori*, based on the gelatinized pileus, voluminous cheilocystidia with yellow sap in ammonia solutions, and an ochraceous

buff spore print as the defining characteristics. The classification of Smith & Thiers (1971) placed the majority of the *Aureoboletus* clade in *Boletus* section *Subtomentosi* subsection *Versicolores* stirps *Roxanae*, but placed *Boletellus projectellus* in the Subsection *Mirabiles* of section *Subtomentosi*. Singer's (1986) concept placed *B. projectellus* in section *Mirabilis* of *Boletellus*, based on the smooth spores, not bluing but often staining lemon yellow tissue, and association with *Pinaceae* and *Fagaceae*. This is in conflict with Smith & Thiers (1971) *Boletellus* concept, which excluded *B. mirabilis* and *B. projectellus*, placing them in *Boletus* instead. However, here we use the Singer taxonomy only because both species are shown to be distantly related to *B. edulis*, not because both species are expected to be closely related to the type of *Boletellus*, *B. ananas* (Fig. 2). There are no apparent morphological characters uniting the *Aureoboletus* clade. Both smooth and ornamented (only *Boletellus schizophorus*) spores occur in the clade; the hymenophore colour is variable: bright lemon yellow to 'pale olive-fresh'; stipe ornamentation ranges from non-reticulate, to longitudinally striated, to highly or coarsely reticulate; spore print colour is reported as a pale ochraceous buff to dark olive brown; gelatinization of the stipe and pileus is found in some species; and non-veiled species and veiled species are present: gelatinous veil, *Aureoboletus thibetanus* and typical veil, *B. projectellus* are present (Smith & Thiers 1971; Singer 1986). In depth taxon sampling is necessary to resolve phylogenetic relationships in this clade.

*Hemileccinum* clade [100/100/1.0]—This well-supported clade is sister to the *Aureoboletus* clade. It contains the type species of *Hemileccinum*, *Hemileccinum impolitum* and *Boletus subglabripes*. This is the first analysis containing both *H. impolitum* and *B. subglabripes*. Previously, *B. subglabripes* had been placed as a close relative of *Leccinellum*, *Leccinum* and *Chamoniaxia* (Desjardin et al. 2008) and *Rossbeevera* (Lebel et al. 2011). Desjardin et al. (2009) placed *H. impolitum* and *Hemileccinum depilatum* as sister to a clade equivalent to the three-gene extended analysis *Xerocomus* clade. Inclusion of *H. depilatum* in this analysis would provide a more conclusive view of the *Hemileccinum* clade. *Hemileccinum* species have been placed in *Boletus*, *Xerocomus*, and *Leccinum* using different generic concepts (Smith & Thiers 1971; Singer 1986; Binder & Besl 2000). Šutara (2008) erected *Hemileccinum* to accommodate species that are smooth spored, with hymenophore trama that is boletoid, lateral stipe stratum that is gelatinous, and stipe scrabrosities.

*Xerocomus* clade [100/100/1.0]—This clade contains the type species of *Xerocomus*, *X. subtomentosus*. Previous studies have reported the distant relationship among the members of the *Xerocomus* clade and members of the *Xerocomellus*, 'badius,' and 'rubellus' clades (Douhan & Rizzo 2003; Peintner et al. 2003). As previous studies have found, Singer's view of the close relationship between *Xerocomus* and *Phylloporus* is upheld (Singer 1986; Binder & Hibbett 2006; Hosen et al. 2012; Neves et al. 2012).

Smith and Thiers's (1971) concept did not differentiate (at the generic level) between *Xerocomus* s.l. (*Xerocomus* and *Xerocomellus* including the 'badius' and 'rubellus' clades) and *Boletus* s.l., stating that the differences in the hypha and hymenophore trama, when combined with an ambiguous definition from other authors (including Singer), caused them to place *Xerocomus* s.l. species in the genus *Boletus*. Molecular

work has helped to differentiate between the two genera, but Šutara (2008) provides a clear morphological framework, which is supported by molecular data, to separate the problematic genera.

The key characteristics of *Xerocomus* are: a non-gelatinized lateral stipe stratum, bacillate ornamented spores, and hymenophore trama of the phylloporoid type (Šutara 2008). This is different from *Boletus* s.str. which generally has a gelatinized lateral stipe stratum with hyphae that are distant from each other, smooth spores, and a boletoid type hymenophore trama. Furthermore, it is separated from *Xerocomellus* based on the presence of longitudinally striate or smooth spores that are never bacillate in *Xerocomellus*, hymenophore trama that is intermediate between boletoid and phylloporoid type, the lack of a lateral stipe stratum (or a very reduced lateral stipe stratum, 30–40 µM compared to 80–200 µM in *Xerocomus* s.str.), and a pileipellis constructed of hyphae with encrusted walls (Šutara 2008).

*Xerocomus* s.str. is separated from *Hemileccinum* by having bacillate spores, a hymenophore trama that is of the phylloporoid type and a lack of stipe scabers or scabrousity that are typical of *Hemileccinum* (Šutara 2008). The morphological distinctions between *Boletus*, *Hemileccinum*, *Xerocomellus*, and *Xerocomus* are succinctly and sufficiently described by Šutara (2008).

**Royoungia clade [100/100/1.0]**—The monotypic Royoungia clade contains two specimens of *Royoungia boletoides* and has previously been shown as closely related, without support, to *Harrya chromapes* (as *Tylopilus*, Desjardin et al. 2009) and to the new genus *Zangia* (Li et al. 2011). Li et al. (2011) demonstrated a sister taxa relationship between *Zangia* species and *T. chromapes* using *nuc*-lsu, *tef1*, mitochondrial large subunit, mitochondrial small subunit, and *atp6*.

Recent work by Halling et al. (2012b) has shown strong support for a clade containing *Zangia*, *Royoungia*, *Harrya*, *Australopilus*, and *Tylopilus* species which are not *Tylopilus* s.str. All things equal, this clade would be sister to the clade B in Figs 1 and 2. The clade appears to be united by pigment in the base of the stipe for stipitate species, and in the peridium of *Royoungia*, though the chemical work to identify the pigment to test for homology across the genera has not been performed. *bicolor* Clade [100/100/1.0]—This clade contains two species, *Boletus bicolor* var. *bicolor* sensu Peck and *Boletus rufomaculatus*. The two members of the clade are characterized by distinct yellow pore surface, with minute pore openings, and stipe colouration and are closely related based on morphology (Bessette et al. 2000; Both 1998; Smith & Thiers 1971). Peck's *B. bicolor* is an illegitimate name; *B. bicolor* was originally described by Raddi in 1807, though the details of what species Raddi named *B. bicolor* have been lost (Peck 1870; Raddi 1807; Snell & Dick 1941). We have chosen to use *Boletus bicolor* sensu Peck, despite the illegitimate naming, as two of the three synonyms available would create a different polytomy in *Xerocomus* and *Boletus* and the third places the species in the now defunct *Ceriomyces* (Murrill 1909; Singer 1947 1986). Correcting this taxonomic confusion necessitates the description of a new genus, but at this time it would be premature to describe a new species based on the small amount of data on hand.

**dupainii clade [71/-/-]**—While this clade has support in only ML methods, it is separated from residual regius clade

by strong support [94/81/0.99]. Only *Boletus calopus* and *Boletus inedulis* species have been previously published in phylogenetic studies (Binder & Hibbett 2006; Desjardin et al. 2009, 2008; Li et al. 2011; Halling et al. 2012a). A clade containing both *B. calopus* and *B. inedulis* is supported in all analysis except for Desjardin et al. (2008), which did not include *B. inedulis*. Species relationships inside *dupainii* are poorly resolved.

**regius clade [100/100/1.0]**—Inside this clade only *Boletus regius* and *Boletus appendiculatus* have been published in molecular studies (Binder & Hibbett 2006; Halling et al. 2012a).

**carminipes clade [82/-/0.96]**—This group contains *Boletus carminipes*, *B. bicolor* var. *borealis*, *Boletus pseudosensibilis*, and *Boletus pulverulentus*. It is a mixture of different sections of both Singer's (1986) concept of the genus *Boletus* and the sections of Smith and Thiers's (1971) concept of the genus *Boletus*.

The above groups and clades are supported [79/73/0.99] as a clade, and are more closely related to each other than the remaining members of the Boletineae, *Pseudoboletus parasiticus*, the *Chalciporus* clade, and the Paxillaceae.

**Pseudoboletus parasiticus**—*Pseudoboletus parasiticus* is placed as sister to the species indicated by node B in Figs 1 and 2 [100/100/1.0]. This is consistent with the study of Desjardin et al. (2009). This bolete is distinctive and difficult to misidentify when found on its host, *Scleroderma citrinum* (Order Boletales, Suborder Sclerodermatinae), and more rarely on other *Scleroderma* spp (Smith & Thiers 1971; Singer 1986). *Pseudoboletus parasiticus* is characterized by yellow–brown fibrils similar in appearance to the scabers of *Leccinum* and *Lecinellum*, an instant cinnabar-orange KOH reaction of the stipe, orange–ochraceous KOH reaction of pileus, and Phylloporus-type trama (Smith & Thiers 1971; Singer 1986; Šutara 1991). However, the defining characteristic is growth from a fruiting body from *Scleroderma* spp.

This clade may contain multiple species. Singer (1986) mentions *Xerocomus astraeicola* as a possible sister species, and the fruiting bodies of *P. parasiticus* were collected near, but not on, *Scleroderma* spp. formed ECM in culture with *Pinus resinosa*, possibly indicating a new species (Richter & Bruhn 1989).

**Chalciporus group [100/100/1.0]**—The Chalciporus group is the earliest branching lineage of the family Boletaceae based on sampling used in this study, which is indicated at node A on Figs 1 and 2. The Chalciporus group includes the monophyletic genus *Chalciporus* and *Buchwaldoboletus lignicola*. The placement of the Chalciporus group in Figs 1 and 2 is supported by previous studies (Binder & Bresinsky 2002b; Binder & Hibbett 2006; Desjardin et al. 2009; Li et al. 2011).

Singer (1986) defined *Chalciporus* as having a solid stipe, a hymenophore that is dull cinnamon red, carmine to wine red or pink, having basal mycelium that is bright yellow in part or in all, and a taste that is either mild or acrid peppery. Furthermore, Singer (1986) describes *Chalciporus* as lacking clamp connections and having adnate to subdecurrent hymenophore, but never arcuate. Smith & Thiers (1971) use similar characters to describe *Chalciporus* species, but place them in the section *Piperati* of *Boletus*.

*Buchwaldoboletus* was described based on the lignicolous habitat, decurrent and arcuate hymenophore, bluing, yellow flesh and yellow basal mycelium (Pilát 1969). In addition, *Buchwaldoboletus* spp. lack clamp connections in the basidocarp,

but clamp connections are present in hyphae of cultures (Pilát 1969; Singer 1986; Watling 2008). This is similar to the description of *Chalciporus*, and the two genera are united by the yellow basal mycelium, lack of veil, and overall hymenophore structure (Pilát 1969); the respective type species of the genera may also share a mycoparasitic nutritional mode.

**Paxillaceae [100/97/0.99]**—The Paxillaceae comprises members of the genus *Paxillus*, and the type species of *Gyrodon* and the monotypic *Paragyrodon sphaerosporus*. *Paxillus* is monophyletic in the Paxillaceae [100/100/1.0] and the Paxillaceae currently contains only ECM fungi.

The family includes morphologically diverse taxa. The genus *Paxillus* comprises only lamellate fungi, while *Gyrodon lividus* produces a tubular hymenophore resembling that of *Boletinellus meruloides* (Sclerodermatinae, Boletales), and *Paragyrodon sphaerosporus* is one of the few species in the Boletineae with a veil (Smith & Thiers 1971; Singer 1986; Binder & Bresinsky 2002a; Binder & Hibbett 2006). Despite the large morphological differences found in the Paxillaceae, all members in this study have clamp connections in the basidiocarp, an uncommon occurrence in the Boletineae (Singer 1986; Binder & Bresinsky 2002a; Watling 2008).

**Hydnomerulius pinastri**—This resupinate, brown-rot fungus was considered as a member of the Boletineae incertae sedis (Binder & Hibbett 2006), and our analyses lack support for its placement in both the three-gene core and extended analyses. It is similar to the members of the Paxillaceae in spore shape and ornamentation, and the presence of clamp connections (Watling 2008).

## Conclusions

The analyses presented here identify clades containing the type species for the following genera: *Aureoboletus*, *Boletus*, *Chalciporus*, *Hemileccinum*, *Leccinellum*, *Leccinum*, *Paxillus*, *Royoungia*, *Strobilomyces*, *Tylopilus*, *Xerocomellus*, and *Xerocomus*. The type species of *Buchwaldoboletus*, *Gyrodon*, *Notholepiota*, *Phylloporus*, *Paragyrodon*, *Pseudoboletus*, *Spongiforma*, and *Xanthoconium* have also been sampled. Three new, strongly supported lineages within the Boletineae were recovered: the anaxoboletus, leccinoid, and hypoboletus groups. These results could form the basis for a genus-level reclassification of the Boletineae. However, to achieve a comprehensive phylogenetic classification of the Boletineae, many more taxa need to be sampled with multiple loci, including taxa from the *Xerocomellus*/*Xerocomus* containing clades, the leccinoid group and *Aureoboletus* clade.

The genus *Boletus* should be restricted to the ‘porcini’ clade; this would reduce the magnitude of *Boletus* from approximately 300 to approximately 30 species (Kirk et al. 2008; Dentinger et al. 2010). We return *Boletus separans* to the genus from *Xanthoconium*, present *Boletus subalpinus* comb. nov., formally transferring *Gastroboletus subalpinus* to *Boletus*, and transfer *Notholepiota areolata* from the Agaricales to *Boletus* s.str., *Boletus semigastroideus* nom. nov. By far the largest challenge to future phylogenetic studies in the Boletineae is resolving the relationships of the roughly 270 species that have been classified in *Boletus* but are not likely to be placed in the ‘porcini’ clade using molecular markers.

## Acknowledgements

This work has been supported by grants from the National Science Foundation, including award DEB-1020421 to REH, DSH and MB. We thank the many collaborators who provided specimens and DNA, including Ernst Both and PB Matheny who provided gDNA for *Boletus semigastroideus*. We would like to thank Duccio Migliorini for preparing the interactions between *Buchwaldoboletus lignicola* and *Phaeolus schweinitzii*. Alfredo Justo provided helpful comments on the manuscript. We thank the two anonymous reviewers who provided helpful comments and suggestions.

Suppl. Fig 1. Phylogenetic relationships among the Boletineae inferred from nuclear large-subunit (nuc-lsu) using RAxML. The tree topology corresponds to the optimal ML topology using the three-gene extended analysis tree topology as a backbone constraint. All BS support values are shown.
